Policy Extraction

Computing Actions from Values

- Let's imagine we have the optimal values $V^*(s)$
- How should we act?
- We need to do an expectimax (one step)

$$\pi^*(s) = \operatorname{argmax}_{a \in A(s)} \sum_{s'} P(s'|s, a) V^*(s')$$

This is called **policy extraction**, since it gets the policy implied by the values

Computing Actions from Q-Values

- Let's imagine we have the optimal q-values:
- How should we act?

$$\pi^*(s) = \arg \max_a Q^*(s, a)$$

Important lesson: actions are easier to select from q-values than values!

Problems with Value Iteration

- Value iteration repeats the Bellman updates:

$$V_{k+1}(s) \leftarrow R(s) + \gamma \max_{a \in A(s)} \sum_{s'} P(s'|s, a) V_k(s')$$

- Problem 1: It's slow – $O(S^2A)$ per iteration
- Problem 2: The “max” at each state rarely changes
- Problem 3: The policy often converges long before the values

Policy Methods

Policy Evaluation

Fixed Policies

Do the optimal action

Do what π says to do

- Expectimax trees max over all actions to compute the optimal values
- If we fixed some policy $\pi(s)$, then the tree would be simpler – only one action per state
 - ... though the tree's value would depend on which policy we fixed

Utilities for a Fixed Policy

- Another basic operation: compute the utility of a state s under a fixed (generally non-optimal) policy
- Define the utility of a state s , under a fixed policy π :
 - $V^\pi(s)$ = expected total discounted rewards starting in s and following π
- Recursive relation (one-step look-ahead / Bellman equation):

$$V^\pi(s) \leftarrow R(s) + \gamma \sum_{s'} P(s'|s, a) V^\pi(s')$$

Example: Policy Evaluation

Always Go Right

Always Go Forward

Example: Policy Evaluation

Always Go Right

Always Go Forward

Bellman Equation (policy) in Matrix Form

- The Bellman equation can be expressed concisely using matrices

$$v = R + \gamma P v$$

- Where v is a column vector with one entry per state

$$\begin{bmatrix} v(1) \\ \vdots \\ v(n) \end{bmatrix} = \begin{bmatrix} \mathcal{R}_1 \\ \vdots \\ \mathcal{R}_n \end{bmatrix} + \gamma \begin{bmatrix} \mathcal{P}_{11} & \dots & \mathcal{P}_{1n} \\ \vdots & & \\ \mathcal{P}_{n1} & \dots & \mathcal{P}_{nn} \end{bmatrix} \begin{bmatrix} v(1) \\ \vdots \\ v(n) \end{bmatrix}$$

Solving the Bellman Equation (policy)

- The Bellman equation (policy) is a linear equation
- It can be solved directly

$$v = \mathcal{R} + \gamma \mathcal{P}v$$

$$(I - \gamma \mathcal{P})v = \mathcal{R}$$

$$v = (I - \gamma \mathcal{P})^{-1} \mathcal{R}$$

- Computational complexity is $O(n^3)$ for n states
- Direct solution only possible for small MRPs

Solving the Bellman Equation (policy)

- Iteration: Turn recursive Bellman equations into updates (like value iteration)

$$V_0^\pi(s) = 0$$

$$V_{k+1}^\pi(s) \leftarrow R(s) + \gamma \sum_{s'} P(s'|s, a) V_k^\pi(s')$$

- Efficiency: $O(S^2)$ per iteration

Policy Iteration

Policy Iteration

- Alternative approach for optimal values:
 - **Step 1: Policy evaluation:** calculate utilities for some fixed policy (not optimal utilities!) until convergence
 - **Step 2: Policy improvement:** update policy using one-step look-ahead with resulting converged (but not optimal!) utilities as future values
 - Repeat steps until policy converges
- This is **policy iteration**
 - It's still optimal!
 - Can converge (much) faster under some conditions

Policy Iteration

- Evaluation: For fixed current policy π , find values with policy evaluation: $U_i = U_{\pi_i}$
 - Iterate until values converge:

$$U_{i+1}(s) \leftarrow R(s) + \gamma \sum_{s'} P(s' | s, \pi_i(s)) U_i(s')$$

- Improvement: For fixed values, get a better policy using policy extraction
 - One-step look-ahead:

$$\pi[s] \leftarrow \operatorname{argmax}_{a \in A(s)} \sum_{s'} P(s' | s, a) U[s']$$

Policy Iteration

```
function POLICY-ITERATION(mdp) returns a policy
  inputs: mdp, an MDP with states  $S$ , actions  $A(s)$ , transition model  $P(s' \mid s, a)$ 
  local variables:  $U$ , a vector of utilities for states in  $S$ , initially zero
                    $\pi$ , a policy vector indexed by state, initially random

  repeat
     $U \leftarrow \text{POLICY-EVALUATION}(\pi, U, \textit{mdp})$ 
    unchanged?  $\leftarrow$  true
    for each state  $s$  in  $S$  do
      if  $\max_{a \in A(s)} \sum_{s'} P(s' \mid s, a) U[s'] > \sum_{s'} P(s' \mid s, \pi[s]) U[s']$  then do
         $\pi[s] \leftarrow \operatorname{argmax}_{a \in A(s)} \sum_{s'} P(s' \mid s, a) U[s']$ 
        unchanged?  $\leftarrow$  false
  until unchanged?
  return  $\pi$ 
```

Figure 17.7 The policy iteration algorithm for calculating an optimal policy.

Policy Iteration

Policy evaluation Estimate v_π
 Iterative policy evaluation

Policy improvement Generate $\pi' \geq \pi$
 Greedy policy improvement

Modified Policy Iteration

- Does policy evaluation need to converge to v^π ?
 - Or should we introduce a stopping condition
 - E.g. epsilon-convergence of value function
 - Or simply stop after k iterations of iterative policy evaluation?
- Why not update policy every iteration? i.e. stop after $k = 1$
 - This is equivalent to value iteration.

Comparison

- Both value iteration and policy iteration compute the same thing (all optimal values)
- In value iteration:
 - Every iteration updates both the values and (implicitly) the policy
 - We don't track the policy, but taking the max over actions implicitly re-computes it
- In policy iteration:
 - We do several passes that update utilities with fixed policy (each pass is fast because we consider only one action, not all of them)
 - After the policy is evaluated, a new policy is chosen (slow like a value iteration pass)
 - The new policy will be better
- Both are dynamic programs for solving MDPs

Summary: MDP Algorithms

- So you want to....
 - Compute optimal values: use value iteration or policy iteration
 - Compute values for a particular policy: use policy evaluation
 - Turn your values into a policy: use policy extraction (one-step lookahead)
- These all look the same!
 - They are all variations of Bellman updates
 - They all use one-step look-ahead expectimax fragments
 - They differ only in whether we plug in a fixed policy or max over actions

Synchronous Dynamic Programming Algorithms

- Both value iteration and policy iteration used synchronous backups
 - i.e. all states are backup up in parallel
- Asynchronous DP backs up states individually, in any order
 - For each selected state, apply the appropriate backup
 - Can significantly reduce computation
 - Guaranteed to converge if all states continue to be selected

Synchronous Dynamic Programming Algorithms

- Three simple ideas for asynchronous dynamic programming:
 - In-place dynamic programming
 - Prioritiesd sweeping
 - Real-time dynamic programming

In-place Dynamic Programming

- Synchronous value iteration stores two copies of value function
 - For all s in S

$$v_{new}(s) \leftarrow \max_{a \in \mathcal{A}} \left(\mathcal{R}_s^a + \gamma \sum_{s' \in \mathcal{S}} \mathcal{P}_{ss'}^a v_{old}(s') \right)$$

$$v_{old} \leftarrow v_{new}$$

- In-place value iteration only stores one copy of value function
 - For all s in S

$$v(s) \leftarrow \max_{a \in \mathcal{A}} \left(\mathcal{R}_s^a + \gamma \sum_{s' \in \mathcal{S}} \mathcal{P}_{ss'}^a v(s') \right)$$

Prioritised Sweeping

- Use magnitude of Bellman error to guide state selection, e.g.

$$\left| \max_{a \in \mathcal{A}} \left(\mathcal{R}_s^a + \gamma \sum_{s' \in \mathcal{S}} \mathcal{P}_{ss'}^a v(s') \right) - v(s) \right|$$

- Backup the state with the largest remaining Bellman error
- Update Bellman error of affected states after each backup
- Can be implemented efficiently by maintaining a priority queue

Real-Time Dynamic Programming

- Idea: only states that are relevant to agent
- Use agent's experience to guide the selection of states
- After each time-step
- Backup the state S_t
-

$$v(S_t) \leftarrow \max_{a \in \mathcal{A}} \left(\mathcal{R}_{S_t}^a + \gamma \sum_{s' \in \mathcal{S}} \mathcal{P}_{S_t s'}^a v(s') \right)$$

- Focus the DP's backups onto parts of states that are most relevant to the agents

Full-Width Backups

- DP uses full-width backups
- For each backup (sync or async)
 - Every successor state and action is considered
 - Using knowledge of the MDP transitions and reward function
- DP is effective for medium-sized problems (millions of states)
- For large problems DP suffers Bellman's curse of dimensionality
 - Number of states $n = |S|$ grows exponentially with number of state variables
- Each one backup can be too expensive then

Sample Backups

- Using sample rewards and sample transitions instead of reward function R and transition dynamics P
- Advantages:
 - Model free: no advance knowledge of MDP required
 - Breaks the curse of dimensionality through sampling
 - Cost of backup is constant, independent of $n = |S|$

Double Bandits

Double-Bandit MDP

- Actions: *Blue*, *Red*
- States: *Win*, Lose

No discount
100 time steps
Both states have
the same value

Offline Planning

- Solving MDPs is offline planning
 - You determine all quantities through computation
 - You need to know the details of the MDP
 - You do not actually play the game!

No discount
100 time steps
Both states have the same value

Value

Play Red 150

Play Blue 100

Let's Play!

\$2 \$2 \$0 \$2 \$2

\$2 \$2 \$0 \$0 \$0

Online Planning

- Rules changed! Red's win chance is different.

Let's Play!

\$0 \$0 \$0 \$2 \$0

\$2 \$0 \$0 \$0 \$0

What Just Happened?

- That wasn't planning, it was learning!
 - Specifically, reinforcement learning
 - There was an MDP, but you couldn't solve it with just computation
 - You needed to actually act to figure it out
- Important ideas in reinforcement learning that came up
 - Exploration: you have to try unknown actions to get information
 - Exploitation: eventually, you have to use what you know
 - Regret: even if you learn intelligently, you make mistakes
 - Sampling: because of chance, you have to try things repeatedly
 - Difficulty: learning can be much harder than solving a known MDP
